Abstract

The knowledge of optical properties of tungsten at high temperatures is of crucial importance in fields such as nuclear fusion and aerospace applications. The optical properties of tungsten are well known at room temperature, but little has been done at temperatures between 300 K and 1000 K in the visible and near-infrared domains. Here, we investigate the temperature dependence of tungsten reflectivity from the ambient to high temperatures (<1000 K) in the 500–1050 nm spectral range, a region where interband transitions make a strong contribution. Experimental measurements, performed via a spectroscopic system coupled with laser remote heating, show that tungsten's reflectivity increases with temperature and wavelength. We have described these dependences through a Fresnel and two Lorentz–Drude models. The Fresnel model accurately reproduces the experimental curve at a given temperature, but it is able to simulate the temperature dependency of reflectivity only thanks to an ad hoc choice of temperature formulae for the refractive indexes. Thus, a less empirical approach, based on Lorentz–Drude models, is preferred to describe the interaction of light and charge carriers in the solid. The first Lorentz–Drude model, which includes a temperature dependency on intraband transitions, fits experimental results only qualitatively. The second Lorentz–Drude model includes in addition a temperature dependency on interband transitions. It is able to reproduce the experimental results quantitatively, highlighting a non-trivial dependence of interband transitions as a function of temperature. Eventually, we use these temperature dependent Lorentz–Drude models to evaluate the total emissivity of tungsten from 300 K to 3500 K, and we compare our experimental and theoretical findings with previous results.

1. Introduction

The study of light interaction with solids deals with how an electromagnetic field interacts with the localized electromagnetic field of the atoms of the solid. The light–matter interaction induces a change on the impinging electromagnetic field just as a temporary or permanent modification of the properties of matter. These changes depend basically on the strength and wavelength of the field of the light and the matter itself. Moreover, external influences on matter, such as temperature, pressure, and other external fields (electrical, magnetic), can change its interaction with light and its optical properties. An accurate knowledge of optical properties of matter is essential both to understanding of the fundamental principles underlying the physical mechanisms behind the laser–matter interaction, and for a wide range of research fields and applications [1], viz. photonics and plasmonics [2–4], optoelectronics [5, 6], nanomedicine [7], infrared pyrometry [8], laser heating [9], and laser damage resistance in optical components [10].

The optical properties of matter are usually described by using Lorentz–Drude models, which treat electrons as damped particles—free (Drude term) or harmonically bound (Lorentz term)—subject to external electric fields. By considering the temperature dependence of electron parameters (i.e. plasma frequency and damping), some works [11, 12] have succeeded in describing theoretically the dependence of optical properties as a function of temperature. We note that these temperature dependent Lorentz–Drude (TDLD) models work very well if the dielectric function is strongly dependent on the intraband/Drude term; for example, optical properties of gold can be well described by a TDLD model for wavelengths $\lambda > 500\text{--}600\text{ nm}$ (2.48–2.06 eV) where the intraband term is dominant with respect to interband terms. Contrastingly, TDLD models start to fail when applied to more complex cases. The reason could lie in the complex nature of the temperature dependence (TD, hereafter) of damping and optical phonons in complex band structures [4, 13]. Recently, some experimental works have preferred a parametric approach to the description of TD of optical properties of matter [14, 15], by varying ad hoc TDLD parameters rather than using analytical formulae.

In this work, we focus our attention on the TD of optical properties of tungsten. The first measurements of tungsten (W) reflectivity at room temperature date back to 1917, [16] but the interest has remained broadly constant over time [6, 17, 18]. In particular, the scientific interest in tungsten has grown recently thanks to its peculiar and useful properties³ for fusion reactors [20, 21] and aerospace applications [22, 23]. This has led to more and more accurate studies of the TD of optical properties of W [23–28]. Nevertheless, the TD of optical properties of W has been measured only for temperatures higher than 1000 K [26], and the agreement between different determinations is not always satisfactory. Optical constants of tungsten have been studied theoretically only at room temperature [6, 18], and—to the best of our knowledge—no scientific works

³ High energy threshold for sputtering, and low erosion under high heat loads [19].

Figure 1. Schematic of the experimental setup: HPL, high power laser; BS, beam splitter; VC, visible camera; IRC, infrared camera; PM, power meter; TC, thermocouple; M1 and M2, silver mirrors; IS, integrating sphere; P, polarizer; SL, supercontinuum laser; FS, fiber-optic spectrometer.

deal with the TD of W from a theoretical point of view. As previously said, the reason could be that usual TDLD models only take into account the temperature dependence of the intraband/Drude term, and thus cannot simulate optical properties in a region where interband terms are also active. This is the case for W in the visible and near-infrared (NIR) domains, where interband transitions produce intense reflectivity drops.

The focus of the present work is twofold: to study experimentally, and to describe theoretically, the temperature dependence of optical properties of W. We first present an experimental measurement of W reflectivity in the optical and NIR wavelength range (500–1050 nm) from room to high temperature (300–925 K). Secondly, we give a quantitative determination of the refractive index and the extinction coefficient of W, and their temperature dependences, by using Fresnel equations. Subsequently, we describe two TDLD models developed in order to study the TD of free carriers and optical phonons in W. The first Lorentz–Drude model includes a temperature dependency on intraband transitions, while the second includes, additionally, a temperature dependency on interband transitions. Eventually, we apply these models in order to estimate the total emissivity in a wide temperature range.

2. Experimental setup

Figure 1 shows the experimental setup developed to perform the experiments. A sample holder in Macor (a machineable glass-ceramic) is located inside a vacuum chamber (base pressure 5×10^{-3} mbar). Vacuum is needed in this type of measurement to prevent oxidation of the sample (see supplementary materials (stacks.iop.org/JPhysD/50/455601/mmedia)). The polycrystalline tungsten sample ($7 \times 7 \times 0.3\text{ mm}^3$) was provided by A.L.M.T. Corp (Japan) with a mirror-like polishing.

The sample can be heated by using a continuous wave high-power laser (AMTRON, HPL in figure 1) system that is based on fiber-coupled GaAs diode emitting at 805 nm (JENOPTIK Laser GmbH). The HPL beam can reach a maximum power of 200 W, and has a quasi-Gaussian profile. The beam diameter is 3 mm at the focal point (30 cm).

In our setup, the heating system and the sample holder are decoupled, since the HPL's head is placed outside the vacuum chamber. This represents a big advantage with respect to the case of coupled systems (e.g. heating resistor [29], heater coil [30], and thermal contact with heating ceramic plate [31]): firstly, samples can be changed rapidly and easily; secondly, the heating system does not impose any constraints about sample sizes. The temperature of the sample is controlled *ex situ* through an InfraRed Camera (FLIR, model A655sc, IRC in figure 1) allowing measurements of temperature in the 230–2300 K range and its spatial distribution on the sample. Calibration of the IRC has been performed by using a type K thermocouple. The IRC works in the 7.5–14 μm spectral range; therefore, we use a BaF₂ viewport with a $\sim 90\%$ transmittance in the considered spectral range. We monitor the position of the incident heating laser on the sample and the mechanical stability of the whole system (sample + sample holder) continuously via a visible-light camera (VC).

Spectroscopic measurements are performed by using a Supercontinuum white light source (LEUKOS, model SM-30–400, SL in figure 1) emitting 100 mW in the 400–2400 nm range. The SL source has a fibred collimated beam (diameter < 1 mm), allowing the angle of incidence on the sample to be changed easily. Moreover, using a collimated source allows all optics to be placed far away from the sample, considerably reducing the detection of its black body radiation [32]. This is a critical issue in the case of high temperature measurements. The SL beam passes through a linear polarizer (Thorlabs, model LPVIS100-MP2, extinction ratio $> 10\,000:1$), and reaches a removable reference silver mirror (Thorlabs, model PF05-03-P01) or the W sample. In the latter case, the SL beam crosses a silica window twice (before and after the W sample), and is sent to a reference silver mirror. From the reference silver mirrors, the beam is sent to an integrating sphere made in Spectralon (LabSphere, IS in figure 1) and reaches the fibred Spectrometer (Avantes, model AvaSpec-ULS2048L, FS in figure 1) through a 1000 μm core fiber (Thorlabs, model M59L01). Since the spectrometer is sensitive in the 200–1100 nm wavelength range, it overlaps with the SL source only in the 400–1100 nm region. Nevertheless, we have performed spectroscopic measurements only in the 500–1050 nm, where the best signal-to-noise ratio has been found.

The W reflectivity is measured by using the following equation

$$R_W = \frac{S_{\text{meas}} - S_{\text{Dark}}}{S_{\text{ref}} - S_{\text{Dark}}} \frac{1}{T_{\text{Siw}}^2}, \quad (1)$$

where S_{meas} and S_{ref} are the spectra obtained by sending the SL beam to the W sample and to the reference mirror respectively; S_{Dark} is the dark spectrum obtained with the SL beam switched off and the sample set to the desired temperature with the HPL heating source ON; T_{Siw} represents the transmission through the fused silica window (see supplementary materials for more details).

Reflectivity has been studied by varying three parameters:

- *Polarization of the SL beam.* Parallel (P) or perpendicular (S) to the plane of incidence.
- *Sample temperature.* Temperature is varied between 300 and 925 K by changing the HPL power sent on sample.
- *Angle of incidence (AOI) of the SL beam.* We have used three angles of incidence with respect to the normal: 20°, 45°, 50°

More details about experimental procedure and error bars are given in the supplementary material.

3. Experimental results

3.1. Reflectivity: polarization and angle dependence at room temperature

We have performed measurements of tungsten reflectivity at room temperature by using two setups: the optical system described in section 2 (hereafter main spectrometer (MS)) and a commercial UV/Vis/NIR spectrometer (Perkin Elmer LAMBDA 1050, hereafter PES). PES cannot be used at any AOI and in the case shown in figure 2, PES has been used with an incidence angle of 8° while we used 20° for MS (in each case the sample is held at room temperature). For this reason, the data obtained with the two setups cannot be quantitatively compared, but can only give an idea of the accuracy of our optical system. As shown in equation (1), reflectivity measurements also rely on the measurement of transmission through the fused silica window. To measure the accuracy of MS, we have performed a first measurement without the fused silica window. The results are shown in the left panel of figure 2. The order of magnitude of reflectivity in PES spectra (solid lines) is very similar to MS spectra: the maximum difference of reflectivity is 0.5% and it varies with wavelength. This amount can be considered as the best value of the MS (without window) accuracy for reflectivity measurements. The observed difference could be due to the incidence angle: actually the most important effect of the AOI on reflectivity spectra is to accentuate the difference between P and S polarizations. In particular the higher is the incidence angle, the lower will be the reflectivity of P-polarized light (at least until the Brewster angle). On the contrary, reflectivity of S-polarized light will increase as a function of the AOI and unpolarized light will only slightly change. All these effects are partially observed by comparing the results of the two setups. We stress that our measurements are coherent with previous works with a maximum difference of 2% probably due to the different type of studied samples [16, 17].

All data presented hereafter have been obtained with the MS setup.

3.2. Temperature dependence of reflectivity

We present in figure 3 the spectral reflectivity of the tungsten sample held at different temperatures (300, 400, 525, 690, 815, and 925 K) for S and P polarizations in the top and bottom panels, respectively. We have studied tungsten reflectivity by

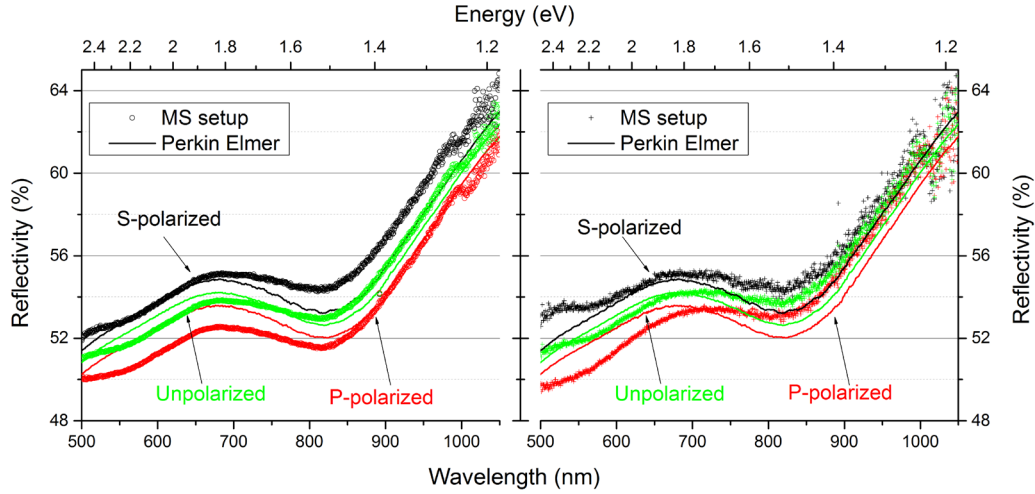

Figure 2. Reflectivity of tungsten for S-polarized (black), P-polarized (red), and unpolarized (green) light as a function of wavelength obtained with the MS setup described in section 2 (dots) and a Perkin Elmer spectrometer (solid lines). Spectra shown in left and right panels are performed without or with fused silica window in MS, respectively.

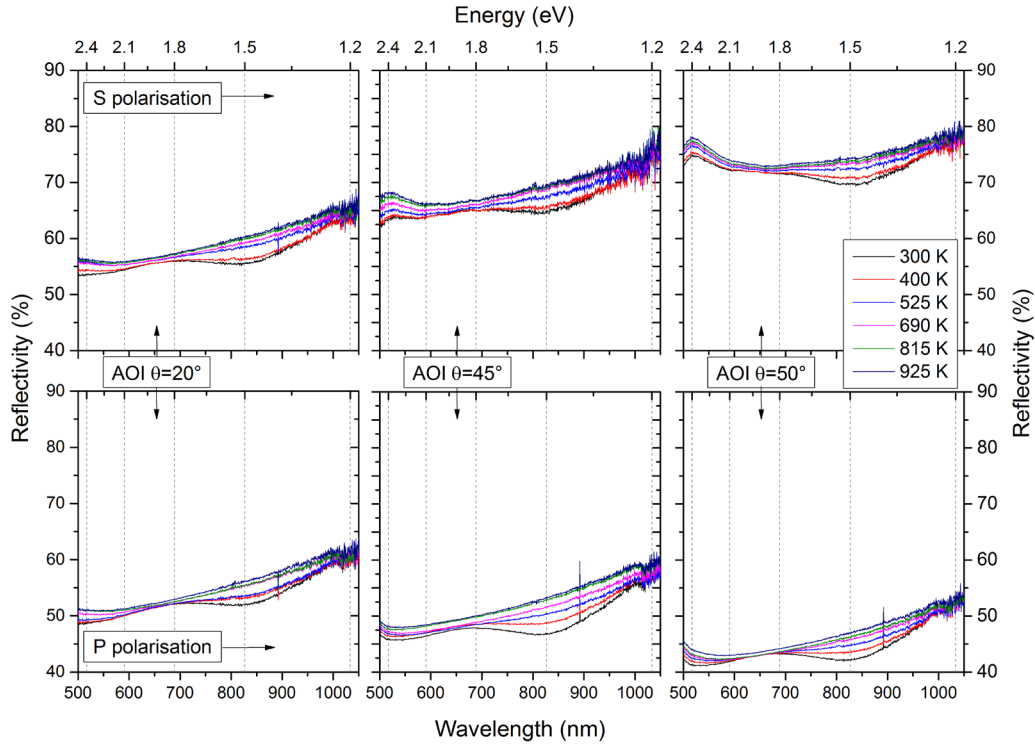

Figure 3. Reflectivity for tungsten of S (top panels) and P-polarized (bottom panels) light at six different temperatures (300, 400, 525, 690, 815, and 925 K) for three incidence angles (from left to right, 20, 45, and 50°) as a function of wavelength.

changing the AOI of light, from the left to the right, to 20, 45 and 50°. Table 1 sums up some of the results discussed in this section. In particular, we list the reflectivity of unpolarized light obtained through the following equation

$$R_{\text{non-pol}} = \frac{R_s + R_p}{2} \quad (2)$$

as a function of temperature and wavelength for the 20° AOI.

At first glance, one can see that an increase of the sample temperature produces an increase of the surface reflectivity. This growth is not linear either as a function of wavelength or temperature. In figure 4, we present the percentage variation

(with respect to room temperature) of reflectivity as a function of temperature for three different wavelengths (550, 650, and 850 nm) in the case of S-polarized light with an AOI of 20°. The highest variation is at 850 nm, where reflectivity has a percentage increase of ~9% between 300 and 925 K. In absolute value that means an increase from 55.9 to 60.8 %. At 650 nm there is a minimum of reflectivity variation, with a percentage increase smaller than 2%. For all other wavelengths, we have measured relative variations ranging between 2% and 9%. Similar behaviors have been observed also for other AOIs and for P-polarized light. The temperature dependence of all these spectra have a similar change in

^bThe value in parentheses represents the uncertainty on the last two digits on reflectivity measurements.

Figure 4. Reflectivity of tungsten for S-polarized light (incidence angle = 20°) at three wavelengths (550, 650, and 850 nm) as a function of temperature.

spectrum shape as a common feature: the *hill* peaked around 700 nm and the *well* at 820 nm visible at room temperature become smoothed, and disappear at 925 K. In other words, spectra become more and more flattened with temperature increase, as we will discuss extensively in section 4 from a theoretical point of view.

4. Models and discussion

In this section, we present the evaluation of the real refractive index n and the extinction index k , and describe the two Lorentz–Drude (LD) models used to fit our experimental results. Firstly, we show how the computational procedure (both for refractive index evaluation and for LD models) is performed in the case of room-temperature data, and subsequently we expand the discussion to the temperature dependent data. We provide from one side the behavior of the refractive index n and extinction coefficient k as functions of temperature, and for the other side

we discuss extensively temperature dependent Lorentz–Drude (TDLD) models, focusing our attention on the role of damping parameters. Finally, we show how TDLD models are able to predict optical properties (i.e. total emissivity) of W in a spectral range not used during the present experiments.

4.1. Temperature independent model

4.1.1. Evaluation of n and k at room temperature from Fresnel reflectance equations. The propagation properties of an electromagnetic field in a medium are commonly described by the dielectric function $\epsilon_r(\lambda)$ (also called relative permittivity), a dimensionless complex number defined as

$$\hat{\epsilon}_r(\lambda) = \epsilon'_r(\lambda) + i \cdot \epsilon''_r(\lambda), \quad (3)$$

related to the refractive index by

$$\hat{n}(\lambda) = \sqrt{\hat{\epsilon}_r(\lambda)} \hat{\mu}_r(\lambda). \quad (4)$$

Also, the refractive index is generally a complex number depending on wavelength:

$$\hat{n}(\lambda) = n(\lambda) + i \cdot k(\lambda), \quad (5)$$

where n is the real refractive index and is related to the light propagation speed, while the imaginary part k , called extinction coefficient, defines the absorption by the medium. The refractive index \hat{n} is related to the amplitudes, phases and polarizations of the reflected and transmitted light that emerge when electromagnetic waves cross the interface between two media with different refractive index. This relation is described by the following equations (i.e. Fresnel equations, FE model)

$$R_s = \left| \frac{n_0 \cos[\theta] - n_1 \sqrt{1 - \left(\frac{n_0}{n_1} \sin[\theta]\right)^2}}{n_0 \cos[\theta] + n_1 \sqrt{1 - \left(\frac{n_0}{n_1} \sin[\theta]\right)^2}} \right|^2, \quad (6)$$

Figure 5. Experimental (points) and theoretical (lines) reflectivity of tungsten at 900 nm as a function of the incidence angle of S (black), P (red) and unpolarized (green) light.

$$R_p = \left| \frac{n_0 \sqrt{1 - \left(\frac{n_0}{n_1} \sin[\theta]\right)^2} - n_1 \cos[\theta]}{n_0 \sqrt{1 - \left(\frac{n_0}{n_1} \sin[\theta]\right)^2} + n_1 \cos[\theta]} \right|^2, \quad (7)$$

where R_s and R_p are the reflectivity of perpendicular and parallel polarizations, n_0 and n_1 are the refractive indexes of the two media, and θ is the AOI of light. These two equations can be used to predict the reflectivity of a medium, given its refractive index. Reciprocally, by measuring R_s and R_p , it is possible to find the couple of values (n , k). It can be done by performing an analytical inversion of Fresnel reflectance equations [33, 34]. Nevertheless, as claimed by Roy *et al* [35], the resulting refractive index values are approximate, and as a consequence the method is not suitable to the task of finding the complex index of refraction. For this reason, we prefer to evaluate n and k numerically, as functions of wavelength. In order to find the best-fit of experimental data, we have varied n and k for each wavelength, trying to minimize the Pearson chi square weighted through the error of experimental data (σ) given below

$$\chi^2 = \sum_{\theta, \text{pol}} \frac{1}{\sigma_{\text{exp}}(\theta, \text{pol})} \left| \frac{R_{\text{exp}}(\theta, \text{pol}) - R_{\text{th}}(\theta, \text{pol})}{R_{\text{th}}(\theta, \text{pol})} \right|^2, \quad (8)$$

where $R_{\text{exp}}(\theta, \text{pol})$ and $R_{\text{th}}(\theta, \text{pol})$ are the experimental and theoretical reflectivities for a given angle and a given polarization, $\sigma_{\text{exp}}(\theta, \text{pol})$ is the experimental reflectivity error for a given angle and a given polarization. Figure 5 shows a comparison between experimental and theoretical reflectivities at 900 nm. Similar results have been obtained at other wavelengths. We have found a value of $\sim 74^\circ$ for the Brewster angle (θ_b) not far from the 77.5° commonly used in the literature [6]. We stress that, depending on the wavelength, θ_b varies slightly, with an average value of 75.2° . In supplementary materials, we provide a table with n and k minimizing equation (8) for wavelength in the 500–1050 nm domain (with a 10 nm step).

Figure 6 shows the simulated reflectivity spectrum obtained with the FE model (red line) compared to the experimental spectrum (dots). The FE model is also compared to the theoretical reflectivity spectrum from Rakic *et al* [6].

Figure 6. Experimental (dots) and theoretical (red line: Fresnel equations model; green dashed line: Rakic *et al* [6]) reflectivity of tungsten at room temperature as a function of wavelength for unpolarized light at AOI = 20° .

We notice two main differences between the two theoretical lines obtained by fitting n and k (red and green line in figure 6). The first difference is the predicted amplitude of reflectivity. Theoretical evaluations of refractive indexes from Rakic *et al* [6] underestimate reflectivity of tungsten by 2–3%. We notice that the experimental data is consistent through two different apparatus (figure 2). Thus, this problem of ‘offset’ between the experimental data and Rakic’s model could be related to the surface properties of tungsten, since Rakic’s work is solely a theoretical work, which does not take into account the presence of the native oxide layer that persists on tungsten up to 2400 K [36]. We point out that we have analyzed the present sample surface oxidation state with Raman spectroscopy, and did not find a significant change of oxidation throughout our measurements (see supplementary materials). Furthermore, we have checked with AFM and SEM the quality of the sample polishing. Nevertheless, we will avoid dealing with the surface property dependence of reflectivity, since a more systematic study, lying outside the scope of this work, should be performed. The other main difference between the two simulated reflectivity spectra is their shape. As already said in the experimental section, reflectivity spectra of tungsten at room temperature presents two peculiar features: the *hill*, peaking at 700 nm, and the *well* at 820 nm. These features exhibit their main evolution in temperature dependent spectra, and are not predicted by Rakic’s refractive indexes. We emphasize that, even if the values of n and k found by Rakic *et al* are not able to simulate the reflectivity of tungsten properly in our spectral domain, they are very powerful in predicting W reflectivity in a very broad wavelength range, from UV (200 nm) to far-IR (12 μm). In any case, we will put aside n and k of Rakic *et al*, since the main goal of this work is to describe the optical properties of tungsten in the 500–1050 nm domain. We note that these two main differences between our model and Rakic’s could be the reasons behind the difference of 2.3° found for θ_b .

The FE model with an ad hoc choice of n and k parameters is able to reproduce accurately the experimental curve at a

Table 2. Values of the LD model parameters.

Oscillator	i	ω_i		f_i		Γ_i	
		Rakic ^a	TW ^b	Rakic	TW	Rakic	TW

Notes: ω_i and Γ_i are given in eV, f_i are dimensionless.

^a From Rakic *et al* [6].

^b This work.

given temperature. However, it is not able to give the temperature dependency of reflectivity, i.e. one must calculate ad hoc parameters every time for any sample temperature or use an empirical formula (see section 4.2.1). Thus, it is desirable to use a less empirical approach where the interaction of light and charge carriers in the solid is physically described, which should allow to develop a temperature dependency based on physical ground. This goal can be achieved by using a Lorentz–Drude model as described in the next section and in section 4.2.2.

4.1.2. Lorentz–Drude model. In this section, we present the Lorentz–Drude (hereafter LD) model developed to describe the electric permittivity of metals, and to simulate the reflectivity of W.

The optical properties of matter are usually described by using Lorentz–Drude models [37] which treat electrons as damped particles, free (Drude term) or harmonically bound (Lorentz term), subject to external electric fields.

In the LD model formalism intraband (Drude) and interband (Lorentz) transitions can be described by several oscillators through the following equation:

$$\hat{\epsilon}_r = 1 - \frac{f_0 \omega_p^2}{\omega(\omega - i\Gamma_0)} + \sum_{i=1}^m \frac{f_i \omega_p^2}{\omega_i^2 - \omega^2 + i\omega \Gamma_i}, \quad (9)$$

where f_0 and Γ_0 are the strength and the damping of the Drude oscillator, while f_i , ω_i , and Γ_i are the strength, frequency, and damping of the Lorentz oscillators, respectively. The reflectivity can be calculated, given the value of $\hat{\epsilon}_r$, through

$$R = \left| \frac{\hat{\epsilon}_r^{1/2} - 1}{\hat{\epsilon}_r^{1/2} + 1} \right|^2. \quad (10)$$

For the sake of clarity we stress that this law is strictly valid for a normal incident beam, while we have used it to fit reflectivity curves at AOI = 20° for unpolarized light. Nevertheless, we point out that, in the case of W, the difference between reflectivity curves at AOIs = 0° and 20° should be ~0.04%, an amount not appreciable with our current experimental setup.

We have fitted our experimental data by using as initial parameters the ω_i , Γ_i , and f_i from Rakic *et al* [6]. In table 2, we list Rakic parameters, as well as the parameters that we found to simulate best our experimentally measured W reflectivity in the 500–1050 nm range at 300 K (T_{room}).

The requirement to obtain a proper fit in the 500–1050 nm spectral range pushes us to slightly change the parameters of Lorentz and Drude oscillators used in Rakic *et al* [6]. The change of the strength of the Drude oscillator is responsible for an overall increase of reflectivity with respect to Rakic's evaluation. The other main difference between the two sets of values is the damping values of Lorentz oscillators. The choice of the present values is able to reproduce the two peculiar features of tungsten reflectivity (i.e. the *hill* peaked at 700 nm and the *well* at 820 nm) that are not predicted by the LD model of Rakic. We stress that each oscillator has an influence in the whole spectrum even if the influence is amplified at ω_i .

4.2. Temperature dependent models

In this section, we present models developed to simulate the temperature dependence of tungsten reflectivity. In section 4.2.1, we discuss an empirical law reproducing the evolution of refractive indexes with W temperature, while in section 4.2.2, we present two temperature dependent Lorentz–Drude models. The physical ground of latter models allow, in section 4.3, to evaluate the temperature dependency of the total emissivity of W in different spectral ranges.

4.2.1. Evaluation of n and k as a function of temperature. In section 4.1.1 we have treated the evaluation of n and k from reflectivity data at room temperature. By following the same procedure described in section 4.1.1, we have fitted the evolution of refractive indexes of tungsten as a function of its temperature. Clearly, refractive indexes depend here both on wavelength and temperature. Both n and k present a decreasing behaviour with temperature. By using two empirical laws, we have fitted the TD dependence of n and k

$$n_{\lambda,T} = n_0(\lambda) + n_1(\lambda) \cdot \exp(-n_2(\lambda) T), \quad (11a)$$

$$k_{\lambda,T} = k_0(\lambda) + k_1(\lambda) \cdot \exp(-k_2(\lambda) T). \quad (11b)$$

Table 3 shows the values of $n_{0,1,2}$ and $k_{0,1,2}$ parameters as a function of wavelength (with a step of 50 nm). All parameters present a wavelength dependence that could be described through a second or third order polynomial. By averaging the values of n and k over all wavelengths (500–1050 nm) for each temperature, we can have a more general idea of the TD of refractive index, as shown in figure 7. The error bars represent standard deviations of n and k values in the considered wavelength range. By fitting mean values of n and k through equations (11a) and (11b), we obtain

$$n_T = 0.562 + 14.272 \cdot \exp(-7.2 \cdot 10^{-3} \cdot T), \quad (12a)$$

$$k_T = 1.462 + 4.099 \cdot \exp(-3.3 \cdot 10^{-3} \cdot T). \quad (12b)$$

We note that the extinction coefficient k decreases more slowly than the real refractive index n , with decay constants τ of 210 and 96 K respectively. We stress that these TD laws for n and k are strictly valid only in the temperature (300 < T < 925 K) and wavelength (500 < λ < 1050 nm) ranges in which they have been obtained.

Table 3. Parameters^a used to fit the temperature dependence of the refractive index n and the extinction coefficient k of tungsten for different wavelengths.

Wavelength nm	Energy eV	Parameters					
		n_0	n_1	$n_2 (10^{-3} \text{ K}^{-1})$	k_0	k_1	$k_2 (10^{-3} \text{ K}^{-1})$
500	2.480	0.427	10.557	5.787	0.904	3.590	0.211
550	2.255	0.573	14.726	7.171	1.210	3.916	0.291
600	2.067	0.615	15.113	7.294	1.237	3.960	0.285
650	1.908	0.614	15.464	7.387	1.405	4.259	0.332
700	1.771	0.637	18.020	7.988	1.582	4.851	0.408
750	1.653	0.588	14.969	7.244	1.491	4.133	0.337
800	1.550	0.573	13.443	6.792	1.365	3.613	0.267
850	1.459	0.631	17.403	7.823	1.721	4.592	0.421
900	1.378	0.586	22.017	8.773	1.694	5.839	0.479
950	1.305	0.549	27.852	9.719	1.679	7.577	0.535
1000	1.240	0.516	24.173	9.245	1.540	4.935	0.364
1050	1.181	0.471	16.565	7.941	1.483	4.481	0.317

^a For n and k respectively, we have used the following laws:

$$n_{\lambda,T} = n_0(\lambda) + n_1(\lambda) \cdot \exp(-n_2(\lambda) T);$$

$$k_{\lambda,T} = k_0(\lambda) + k_1(\lambda) \cdot \exp(-k_2(\lambda) T).$$

4.2.2. Temperature dependent LD models. Here, we present two modifications of the LD model presented in section 4.1.2 to take into account the temperature dependence. The main modification that has to be considered in equation (9) concerns damping factors. Actually, for a bulk metallic sample, the motion of electrons in the conduction band can undergo different damping mechanisms. The first source of damping for electrons is the electron–electron scattering Γ_{e-e} . This process is well known [38, 39] and Lawrence and Wilkins [40, 41] have described its frequency and temperature dependencies using the following equation

$$\Gamma_{e-e} = \frac{\pi^3}{12 \hbar E_f} \left[(k_b T)^2 + \left(\frac{\hbar \omega}{2 \pi} \right)^2 \right], \quad (13)$$

where E_f is the Fermi energy, k_b and \hbar are the Boltzmann and Planck constants, respectively. We note that in the optical spectral range the temperature dependent term turns to be negligible with respect to its frequency dependent counterpart [11, 12].

The second damping mechanism is the electron–phonon scattering Γ_{e-ph} . This term is the most important in describing the TD of damping. Its expression was derived for free electrons (intraband/Drude term) by Holstein [42, 43] and it is still extensively studied in different fields of research [4, 44]. A possible expression is given below (see Alabastri *et al* [12] for more details)

$$\Gamma_{e-ph} = \Gamma_0 \left(\frac{2}{5} + 4 \left(\frac{T}{\theta} \right)^5 \int_0^{\theta/T} \frac{z^4 dz}{e^z - 1} \right). \quad (14)$$

The TDLD model including a temperature dependence on the intraband/Drude term, i.e. the intra-TDLD model, is thus described by

$$\hat{\epsilon}_r(T) = 1 - \frac{f_0 \omega_p(T)^2}{\omega(\omega - i\Gamma(T))} + \sum_{i=1}^m \frac{f_i \omega_p(T)^2}{\omega_i^2 - \omega^2 + i\omega\Gamma_i}. \quad (15)$$

**Figure 7.** Temperature dependence of averaged (over 500–1050 nm) values of n and k . Lines are plotted from equations (12a) and (12b) (see text).

Here, the temperature dependence of the plasma frequency includes a reduced electronic density due to the thermal volume expansion [45], and is given by

$$\omega_p(T) = \frac{\omega_p}{\sqrt{1 + \gamma(T - T_{\text{room}})}}, \quad (16)$$

where γ is the thermal expansion coefficient of tungsten ($4.3 \times 10^{-6} \text{ K}^{-1}$). In order to reproduce the damping parameter of the LD model at room temperature, we can write the damping parameter by subtracting the contribution calculated at room temperature as follows

$$\Gamma(T) = \Gamma_0 + \Gamma(T) - \Gamma(T_{\text{room}}). \quad (17)$$

The results of the intra-TDLD model are shown on the left panel in figure 8. In particular, we present the comparison of experimental (dots) and theoretical (solid lines) results, obtained for unpolarized light with an AOI of 20° at six temperatures: 300, 400, 525, 690, 815, and 925 K. As evident, the intra-TDLD model is not able to fit quantitatively the measured spectra, but it only succeeds in reproducing the overall behavior of reflectivity, i.e. its increase as a function of

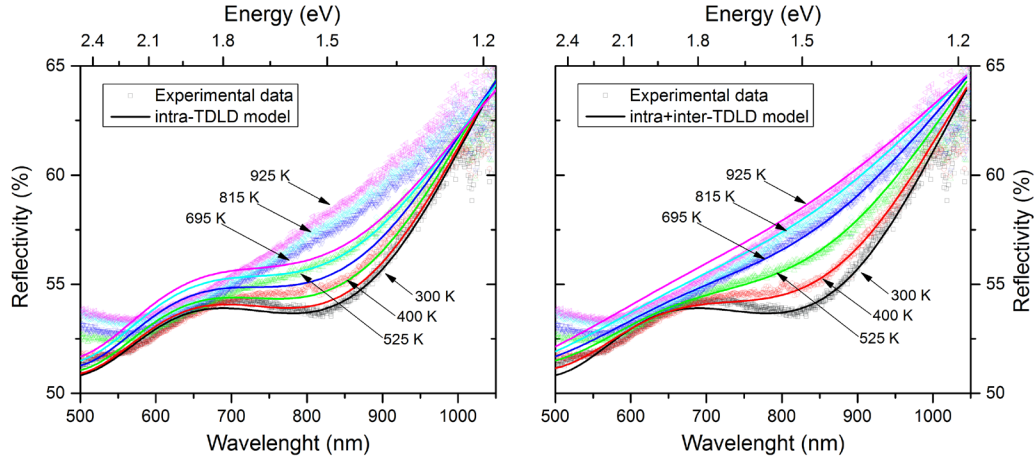

Figure 8. Measured and calculated reflectivity of unpolarized light at 20° of AOI. Lines are obtained by using the intra-TDLD model (left panel) and the intra + inter-TDLD model (right panel) for six different temperatures (300, 400, 525, 695, 815, and 925 K).

temperature. The difference of absolute reflectivity between the model and experiments varies as a function of wavelength. At room temperature, it is 0.1% (absolute value) at ~850 nm, while it reaches a maximum value of ~2.4% for spectra taken at 925 K.

As said in section 3.2, the most evident effect of the temperature increase is to flatten the *hill* peaking around 700 nm and the *well* at 820 nm, present in the room temperature spectra. In equation (15), we can note that the interband terms do not contain any temperature dependence, and this could be the reason for the quantitative difference between theoretical and experimental spectra. Thus, the flattening of the reflectivity spectrum observed experimentally could be due to a different response of Lorentz oscillators to a temperature increase. Different works [46, 47], studying gold nanoparticles, claimed that interband terms should have minimal or no effect on plasmon absorption with temperature since interband transition energies (typically of the order of the eV) are very high compared to vibrational energy ($\sim 10^{-2}$ eV). Our results, and some recent experimental works performed on different materials (ultrathin Au films [15], bis(ethylenedithio)tetrathiafulvalene [48], BSTS [49], LiInSe [14]), suggest a temperature dependence for interband terms contradicting the previous statement. Usually a parametric approach is preferred [14, 48] to fit the experimental observations, performed by an ad hoc change of Lorentz–Drude parameters. However, we preferred to reduce the number of free parameters, keeping the TD for Drude parameters. We have used a simple mechanical model [50] to consider the temperature dependence of Lorentz oscillators. In this so-called intra + inter-TDLD model, we consider that Lorentz oscillators experience a frictional force, modeled as a collisional resistance, increasing as a function of temperature. This is consistent with the fact that the probability of electron–phonon scattering increases as a function of temperature since, for a fixed frequency, the number of phonons increases following

$$\langle n_{\text{phonons}} \rangle = \frac{1}{\exp(\frac{\hbar\omega}{k_b T}) - 1}. \quad (18)$$

Table 4. Values of resonance frequencies and damping values calculated with equations (19) and (21) (expressed in eV) for Lorentz oscillators at sample temperatures indicated in figure 8.

Oscillator parameters	Temperature (K)					
	300	400	525	695	815	925
ω_{Lorentz1}	0.940	0.934	0.926	0.919	0.914	0.909
ω_{Lorentz2}	1.860	1.847	1.834	1.818	1.808	1.799
ω_{Lorentz3}	3.350	3.327	3.303	3.274	3.256	3.240
ω_{Lorentz4}	7.700	7.648	7.592	7.526	7.748	7.448
Γ_{Lorentz1}	0.720	0.787	0.861	0.949	1.003	1.049
Γ_{Lorentz2}	1.330	1.455	1.590	3.212	1.853	1.939
Γ_{Lorentz3}	2.440	2.669	2.917	1.751	3.399	3.558
Γ_{Lorentz4}	2.800	3.062	3.348	3.686	3.900	4.083

It is equivalent to say that atoms are vibrating more with the increase of temperature and they are more likely to be hit by bound electrons, increasing as a consequence the resistance of the metal. According to this model, [50] and to equation (17), the damping will increase with temperature as:

$$\Gamma_i(T) = \Gamma_i + \alpha(\sqrt{T} - \sqrt{T_{\text{room}}}), \quad (19)$$

where α is a parameter expressed in $\text{eV} \cdot \text{K}^{-1/2}$. From the denominator of the Lorentz term in equation (15), we find that

$$\omega_i^2 = \omega(\omega - i\Gamma_i) \propto -\sqrt{T}, \quad (20)$$

and the resonance frequency of Lorentz oscillators can be written as follows

$$\omega_i^2(T) = \omega_i^2 - \beta(\sqrt{T} - \sqrt{T_{\text{room}}}), \quad (21)$$

where β is a parameter expressed in $\text{eV}^2 \cdot \text{K}^{-1/2}$. The intra + inter-TDLD model is thus described by

$$\hat{\epsilon}_r(T) = 1 - \frac{f_0 \omega_p(T)^2}{\omega(\omega - i\Gamma(T))} + \sum_{i=1}^m \frac{f_i \omega_p(T)^2}{\omega_i(T)^2 - \omega^2 + i\omega\Gamma_i(T)}. \quad (22)$$

Figure 9. Calculated or measured total emissivity of tungsten from different references. Solid lines and full dots have been obtained for different spectral ranges through the intra-TDLD and the intra + inter-TDLD models, respectively. Open blue symbols are taken from Matsumoto *et al* [26] (squares), Worthing [51] (pentagons) and Rudkin [52] (stars). Blue dashed curve is a fit of data from Matsumoto *et al* [26]. Open circles and triangles are taken from Brodu *et al* [23].

As evident from the right panel in figure 8, the intra + inter-TDLD model is able to reproduce quantitatively the flatten of reflectivity curves through the two supplementary TD Lorentz terms in equation (22). These curves have been obtained by using $\alpha = 3.5 \cdot 10^{-2} \text{ eV} \cdot \text{K}^{-1/2}$ and $\beta = 2.5 \cdot 10^{-3} \text{ eV}^2 \cdot \text{K}^{-1/2}$. We list in table 4 resonance frequencies and damping values (expressed in eV) for Lorentz oscillators as a function of temperature. Therefore, the use of a frictional model to describe the temperature dependency of Lorentz oscillators in a Lorentz–Drude model seems to be an interesting subject of study for future works.

4.3. From reflectivity to emissivity

In the previous section, we have focused our attention on a Lorentz–Drude model which includes temperature dependences on both intraband and interband terms (intra + inter-TDLD) that is able to reproduce reflectivity spectra quantitatively. This new model can also be used to infer information about spectral emissivity. Actually, it is well known that for an opaque material (i.e. transmission = 0), reflectivity and spectral emissivity are linked by the following relation

$$\epsilon_s(\lambda) = 1 - R(\lambda). \quad (23)$$

In turn, it is possible to find the total emissivity from spectral emissivity through the following equation

$$\epsilon_{\text{tot}} = \frac{\int_{\lambda_1}^{\lambda_2} \epsilon_s(\lambda) \lambda^{-5} \cdot \exp\left[\frac{c_2}{\lambda T}\right]^{-1} d\lambda}{\int_{\lambda_1}^{\lambda_2} \lambda^{-5} \cdot \exp\left[\frac{c_2}{\lambda T}\right]^{-1} d\lambda}, \quad (24)$$

where c_2 is the second Planck radiation constant; λ_1 and λ_2 are the limits of integration. By using equations (23) and (24), we have chosen three different couples of integration limits, two ($0.6 < \lambda < 2.8 \mu\text{m}$ and $0.6 < \lambda < 40$

μm), to perform a direct comparison with reflectivity data of W annealed at 1700 K from Brodu *et al* [23] and a third ($0.4 < \lambda < 300 \mu\text{m}$) to do a direct comparison with hemispherical total emissivity measurements from Matsumoto *et al* [26], Worthing [51], and Rudkin [52]. To evaluate the total emissivity, we have used both the intra-TDLD model and the intra + inter-TDLD model (solid lines and full dots in figure 9, respectively).

Total emissivity is proportional to the integral of ϵ_s over the considered spectral range, and thus it is inversely proportional to the reflectivity. This means that ϵ_{tot} evaluated in the visible and near-IR will be higher than ϵ_{tot} in the IR or far-IR. This is confirmed by inspection of the solid red line or full red circles ($0.6\text{--}2.8 \mu\text{m}$) and solid green line or full green triangles ($0.6\text{--}40 \mu\text{m}$) in figure 9. Moreover, we see that $\epsilon_{\text{tot}}(0.6\text{--}40 \mu\text{m})$ is in good agreement with results of Brodu *et al* [23] (open green triangles). In contrast, our data do not follow the same behavior of $\epsilon_{\text{tot}}(0.6\text{--}2.8 \mu\text{m})$ found by Brodu *et al* [23] (open red circles). Surprisingly, these data do not present any temperature dependence, presenting an almost constant value of $\epsilon_{\text{tot}} \sim 0.4$ in the 1000–1700 K temperature range, and contradict our experimental results. We stress that our reflectivity measurements did not present any hysteresis, i.e. measurements performed at 300 K are identical before and after measurements at 925 K, consistent with the negligible oxidation of our samples (see supplementary material). The discrepancy of our results with those of Brodu *et al* for this wavelength range is therefore not understood for the moment.

Figure 9 also shows data from Matsumoto *et al* [26] (squares), Worthing [51] (pentagons) and Rudkin [52] (stars). These data cannot easily be compared to our data, since the physical quantity measured in these works is slightly different from the total emissivity as defined in equation (24). Emissivity measurement in these works is based on the heat balance of the heated sample in a brief steady-state period. In other words, at temperatures higher than 1500 K, heat loss from the sample happens essentially by thermal radiation, and the electrical power imparted to the sample to heat it is equal to the power loss from the sample. So, by measuring the current and voltage drop across sample, it is possible to derive emissivity from the Stephan–Boltzmann law. This type of measurement is not dependent on the wavelength range, but it considers the whole black body radiation. For this reason, we have calculated the emissivity through the intra-TDLD and the intra + inter-TDLD models by extending the spectral range from $0.4 \mu\text{m}$ to $300 \mu\text{m}$ (solid blue line and blue full triangles). Results obtained through the intra-TDLD and the intra + inter-TDLD models are in good agreement with the fit of data from Matsumoto *et al* [26] at low temperatures (below 1000 K). On the other hand our calculations seem to overestimate $\epsilon_{\text{tot}}(0.4\text{--}300 \mu\text{m})$ with respect to previous results at high temperatures (2500–3500 K). We may explain this difference by considering that in this temperature range the solid–liquid phase transition could activate different physical mechanisms (not considered in our models), and thus induce a different light–matter interaction.

5. Summary and outlook

In the present work, the optical properties of tungsten have been studied as a function of its temperature. We have shown experimentally that the tungsten reflectivity shows a temperature dependence in a spectral range (500–1050 nm) and temperature domain (300–925 K) never studied in the literature until now. The temperature increase induces a non-linear reflectivity variation as a function of wavelength: we have measured between 300 and 925 K relative variations between 2% (at 650 nm) and 9% (at 850 nm).

We have developed two different models to simulate the observed temperature dependence of tungsten optical properties. The first, based on Fresnel equations, is able to reproduce the experimental curve accurately at a given temperature, but it is able to simulate the temperature dependency of reflectivity only thanks to an ad hoc choice of temperature formula for refractive indexes. The second model is based on the Lorentz–Drude formalism, and uses a less empirical approach to describe the interaction of light and charge carriers in the solid. A first version of the temperature dependent Lorentz–Drude model includes the temperature dependence only in the Drude term (intraband transitions) and it is able to reproduce qualitatively the increase of W reflectivity as a function of temperature. A second version of the model has been developed, which describes the temperature dependence in the Lorentz terms (interband transitions) as a frictional force exerted on bound electrons. This model shows better agreement with experimental results than the first version. Thanks to the quantitative agreement between our reflectivity measurements and this new Lorentz–Drude model, we have shown that interband transitions should present a temperature dependence. We stress that this new result is not in disagreement with literature. Actually, previous experimental and theoretical works have studied temperature dependence of optical properties of metals in a spectral range where only intraband transitions are strongly active (e.g. Au in the visible domain, or W in the IR domain), while our work deals with a system (W/visible) where interband transitions can be probed.

Once the model has been validated in the spectral and temperature domain used for experiments, it has been extended up to 300 μm and 3500 K to evaluate the total emissivity of W. Our theoretical results are in good agreement with emissivity measurements performed at high temperature (from 1000 to 2500 K) and for the first time deal with the temperature behaviour of total emissivity at temperatures below 1000 K.

Our results are of particular interest to the fusion [20, 21] and aerospace communities [22, 23], since tungsten, thanks to its peculiar and useful properties, is suitable for environments where high photon and particle fluxes are present. For example, tungsten has been proposed for use in spacecraft sent near the sun (e.g. NASA's Solar Probe Plus mission) or in the divertor of future fusion devices (e.g. ITER). In the case of ITER, the working temperature range of the divertor starts around 345 K, making our study fully relevant. Additionally, a better knowledge of tungsten properties (optical and mechanical) is needed in order to prevent security issues or failing of aerospace missions [53–56].

We consider in the future to enlarge these experimental studies to the IR spectral range and for temperatures up to 2000 K. To this end, we are developing a UHV setup to prevent oxidation of the sample at temperatures above 1000 K. This development will enable the simultaneous study of the influence of oxidation state, morphology, and temperature on optical properties of different refractory metals, such as tungsten or molybdenum.

Acknowledgments

This work has been carried out thanks to the support of the A*MIDEX project (no. ANR-11-IDEX-0001-02) funded by the 'Investissements d'Avenir' French Government program, managed by the French National Research agency (ANR). MM thanks A Alabastri for fruitful discussion about the temperature dependent Lorentz Drude model.
